Abstract

Aims Increased visit-to-visit glycaemic variability is independently associated with adverse outcomes in Type 2 diabetes. Our aim was to identify the patient characteristics associated with raised visit-to-visit glycaemic variability in people with Type 2 diabetes.

Methods A case-control study was conducted to establish associations between HbA_{1c} variability and clinical covariates in 10 130 people with Type 2 diabetes. Variability was calculated by two metrics [SD and coefficient of variation (CV)] from a minimum of four HbA_{1c} readings obtained over a 4-year period. High and low variability groups were defined as the top and bottom tertile of the SD or CV, and used in logistic regression analyses including a number of clinical and biochemical covariates. The analyses were stratified into low mean (< 53 mmol/mol; 7%) and high mean (≥ 53 mmol/mol; 7%) HbA_{1c} groups.

Results Findings were consistent across both HbA_{1c} groups and variability metrics. Treatment, independent of other factors, was the most strongly associated covariate for the risk of high HbA_{1c} variability. A six-fold increased risk was observed in the low HbA_{1c} group, between the most and least intense treatment regimens ($P < 0.001$). Similar findings were present in the high HbA_{1c} group with a three-fold increase in risk ($P < 0.001$). In addition, male gender, younger age, reduced HDL-cholesterol and increased BMI were all found to be independently associated with raised visit-to-visit glycaemic variability.

Conclusions Intensive treatment resulting in low mean HbA_{1c} was associated with marked increase in HbA_{1c} variability. Irrespective of diabetes control, the greatest visit-to-visit variability was observed in young, insulin resistant men.

Diabet. Med. 35, 262–269 (2018)

Introduction

Pivotal studies over the years have demonstrated the beneficial effects of lowering HbA_{1c} on both micro- and macrovascular complications in Type 2 diabetes [1,2]. However, on-going debate exists as to whether other factors, such as glycaemic variability, play a contributory role in the adverse outcomes of diabetes.

Glycaemic variability is the measure of glycaemic fluctuations over a given time. Clinically, it is an umbrella term for two distinct measurements: intraday variability (short-term)

and visit-to-visit variability (long-term). HbA_{1c} is most often used as the measure of glycaemia in the latter. Currently, no 'gold standard' metric exists to measure HbA_{1c} variability, however, it is most commonly expressed as either the standard deviation (SD) or coefficient of variation (CV) of the glycaemia measures.

Many studies in Type 2 diabetes cohorts have shown positive associations between raised visit-to-visit variability and adverse outcomes, independent of mean HbA_{1c} level. A recent meta-analysis identified that renal disease, cardiovascular disease and mortality were all independently associated with raised HbA_{1c} variability [3]. This analysis included 13 studies, the largest of which contained > 4000 participants [4]. Research in the field of intraday variability has shown that certain patient features and clinical factors are associated with raised short-term glycaemic variability [5–8]. However, we identified no similar studies in the field of long-term glycaemic variability.

What's new?

- Increased visit-to-visit HbA_{1c} variability has previously been associated with increased risk of adverse outcomes, including microvascular and macrovascular disease.
- We determined the patient characteristics associated with raised visit-to-visit glycaemic variability, independent of the mean HbA_{1c} level and established that these people with highly variable Type 2 diabetes have increased cardiovascular disease risk factors including male gender, raised BMI and reduced HDL-cholesterol compared with those with low variability.
- People with Type 2 diabetes receiving greater intensity of treatment (e.g. insulin treatment or triple oral therapy) have greater visit-to-visit variability than those who are diet or monotherapy treated.

The detrimental consequences of high intraday variability have been mapped at a cellular level and are well documented [9–12]. The cellular effects of elevated HbA_{1c} variability are unknown, which gives rise to the possibility that two distinct biological processes are occurring. Establishing whether the same patient characteristics are associated with both raised intraday and HbA_{1c} variability is of interest because the findings could provide an insight into the biological processes responsible for increased HbA_{1c} variability and its associated adverse outcomes.

The aim of our research was to identify the patient characteristics associated with the risk of raised HbA_{1c} variability in a large Type 2 diabetes cohort.

Participants and methods

Study setting and design

A case–control study of HbA_{1c} variability was conducted in Tayside and Fife (Scotland, UK). Data were gathered from the Scottish Care Information-Diabetes Collaboration (SCI-DC); the electronic health record system used in Scotland for people with diabetes. We identified a source population of 13 285 individuals with Type 2 diabetes. Biochemical, demographic and prescribing data were available for these participants across a 20-year period since 1994.

Participants with at least four HbA_{1c} recordings within a 4-year window of time between 1 January 2010 and 1 January 2014 were included in this study (Fig. 1). Baseline data on covariates were gathered at 1 January 2010 (\pm 6 months). If a participant had more than one covariate recording, the mean of these values was calculated. For those with more than one treatment therapy recorded, the latest listed was used for the analysis; this treatment was the most likely to be continued due to the stepwise progression of diabetes management.

Each participant had their glycaemic variability defined by two metrics; the SD and the CV, which was $100 \times \text{SD}/\text{mean HbA}_{1c}$. Two HbA_{1c} variability groups were then constructed encompassing the top tertile of the distribution (high variability = cases) and bottom tertile of the distribution (low variability = controls) respectively (Fig. 2). This process was carried out for both SD and CV.

Statistical analyses

Analysis of variance (ANOVA) and chi-square tests were used to compare means and frequencies among subgroups of participants respectively. Tests of association with HbA_{1c} variability (coded as binary, high = case vs. low = control) were performed using unconditional logistic regression models. Univariate models were used to determine the patient characteristics associated with glycaemic variability, and potential determinants (gender, age, duration of Type 2 diabetes, diabetes treatment, HDL-cholesterol, BMI, social deprivation and number of HbA_{1c} readings) were considered in the analysis. We then developed a multivariate model, including covariates where the univariate *P*-value for the trait association was ≤ 0.2 [13]. This analysis was carried out for both variability metrics (i.e. SD and CV). We used the goodness-of-fit approach described by Hosmer and Lemeshow to test how well the derived model fitted the data [14]. Two-way interactions were additionally tested for between participant gender and the other covariates included in our final multivariate model.

Preliminary analyses revealed a strong positive association between mean HbA_{1c} level and high variability. Subsequently, the data were stratified into two groups based upon mean HbA_{1c} level. The HbA_{1c} value of 53 mmol/mol (7.0%) was selected as the cut-off, creating a low mean HbA_{1c} group (< 53 mmol/mol; 7.0%) and a high mean HbA_{1c} group (≥ 53 mmol/mol; 7.0%) which were used in all subsequent analyses. This HbA_{1c} cut-off of 53 mmol/mol (7.0%) was chosen for two reasons: first, it split our sample distribution into two groups with a large number of participants in each; and second, it is a clinical target for HbA_{1c} treatment in people with Type 2 diabetes [15].

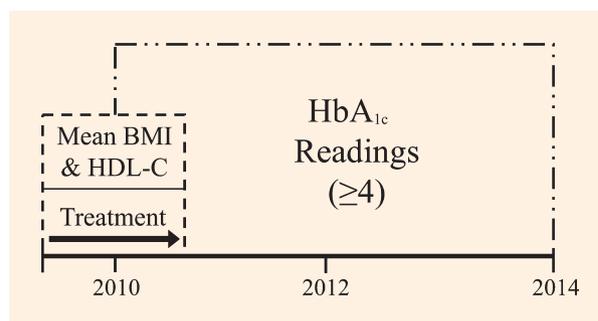

FIGURE 1 Depiction of the retrospective data collection process.

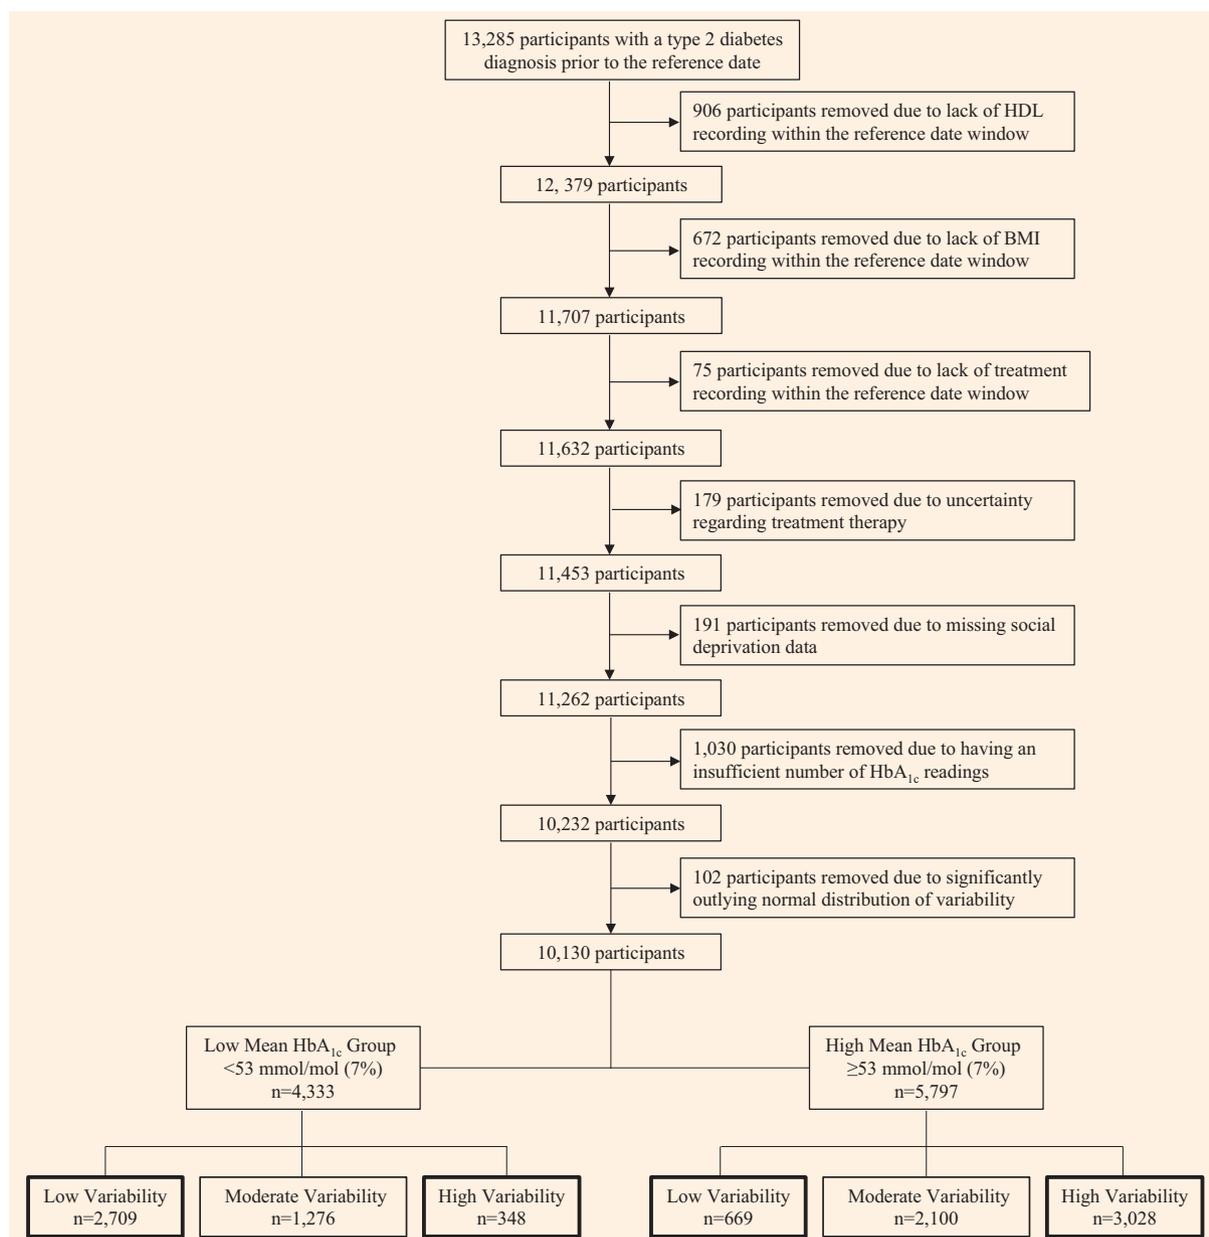

FIGURE 2 Flow chart showing how the participant sub-groups were created when variability was defined as the standard deviation of the HbA_{1c} readings.

Sensitivity analyses were performed to determine if extreme mean HbA_{1c} values were driving the analyses and whether insulin treatment, in isolation, was associated with increased variability. The first analysis removed all participants with a mean HbA_{1c} < 48 mmol/mol (6.5%) and > 75 mmol/mol (9.0%) from the cohort, after which the previously described multivariate analysis was carried out. The second sensitivity analysis was a whole sample multivariate analysis in which the three previously used treatment groups were broken down into five individual categories to specifically focus on any potential associations between the use of insulin and variability. The final sensitivity analysis

carried out addressed the issue of therapy changes across the 4-year HbA_{1c} collection window. Participants who had a different final treatment from their baseline recording were removed prior to the creation of the model. Statistical analyses were conducted using STATA/SE version 14 software (StataCorp, College Station, TX, USA), and the statistical significance level set at $P < 0.05$.

Results

Some 10 130 participants were included in the analysis and their baseline characteristics are shown in Table 1. A total of

Table 1 Baseline characteristics

Characteristic	All (<i>n</i> = 10 130)	Low variability controls (<i>n</i> = 3378)	High variability cases (<i>n</i> = 3376)	P value (low vs high)
Gender, <i>n</i> (%)				< 0.001

HbA _{1c} (%)	7.4 (1.1)	6.5 (0.7)	8.2 (1.1)	< 0.001

Values are reported as the mean (SD), unless indicated otherwise.

3378 participants were categorised as having low HbA_{1c} variability, of whom 2709 had a mean HbA_{1c} < 53 mmol/mol (7.0%) and 669 had a mean HbA_{1c} ≥ 53 mmol/mol (7.0%). The high HbA_{1c} variability group contained 3376 participants, of whom 348 had a mean HbA_{1c} < 53 mmol/mol (7.0%) and 3028 had a mean HbA_{1c} ≥ 53 mmol/mol (7.0%). The characteristics of the 1030 people with Type 2 diabetes excluded from the analysis due to an insufficient number of HbA_{1c} readings are shown in Table S1.

Similar results were observed using both the SD and CV as a measure of HbA_{1c} variability. However, the 'goodness of fit' score in the logistic regression models was superior when using the SD compared to the CV. Therefore, the results of the analysis are presented purely for the SD.

Univariate logistic regression revealed that a number of covariates were associated with HbA_{1c} variability in both the low and high mean HbA_{1c} strata (Table S2). The low mean HbA_{1c} analysis found that: men had greater odds of having high HbA_{1c} variability compared with women [odds ratio (OR) 1.45, 95% CI 1.16–1.82, *P* = 0.001]; participants aged < 55 years were more likely to be highly variable compared with those aged 75 years and older (OR 3.05, 95% CI 2.12–4.39, *P* < 0.001); and both lower HDL-cholesterol and higher BMI were associated with raised HbA_{1c} variability. Participants treated with medication had markedly increased variability compared with those whose diabetes was diet controlled. The odds of high HbA_{1c} variability were greater in the 'triple or insulin' group compared with the 'mono or dual' therapy group. Finally, a short duration of diabetes was marginally associated with lower risk of high HbA_{1c} variability. Similar results were seen in the high mean HbA_{1c} group, although the previously observed protective effect

regarding duration of Type 2 diabetes was not significant in this analysis.

The results of the stratified multivariate logistic regression models are shown in Table 2. The models were adjusted for social deprivation and the number of HbA_{1c} measures. These multivariate models are consistent with the univariate analysis showing that the previous findings are independent of other variables. The goodness-of-fit scores for the low ($\chi^2 = 1736.72$, *P* = 0.82) and high ($\chi^2 = 2219.15$, *P* = 0.72) mean HbA_{1c} strata models indicated that both fitted the data well. In addition, none of the two-way interactions tested between gender and other covariates were statistically significant. Table 2 shows that those in the 'triple or insulin' treatment group were over six times more likely to be highly variable than those whose diabetes was diet treated in the low mean HbA_{1c} strata (OR = 6.64, 95% CI 3.72–11.86, *P* < 0.001). This large increase in risk was also observed in the high mean HbA_{1c} group with a greater than three-fold increase compared with those whose diabetes was diet treated (OR 3.15, 95% CI 2.21–4.47, *P* < 0.001). In addition to this, younger people with Type 2 diabetes when compared with their older counterparts remained far more likely to be highly variable. In both HbA_{1c} strata those < 55 years old were more than twice as likely to have high HbA_{1c} variability compared to those aged 75 and older.

Some 6763 participants were included in the first sensitivity analysis, which removed those with low mean HbA_{1c} (< 48 mmol/mol; 6.5%) and high mean HbA_{1c} (> 75 mmol/mol; 9%). The low variability group contained 2255 participants, of whom 1110 had a mean HbA_{1c} < 53 mmol/mol (7.0%) and 1145 had a mean HbA_{1c} ≥ 53 mmol/mol (7.0%).

Table 2 Multivariate whole sample analysis showing the odds of being highly variable

Variable	Low mean HbA _{1c} (<i>n</i> = 3057)		High mean HbA _{1c} (<i>n</i> = 3697)

Adjusted for social deprivation and number of readings.

The high variability group in this analysis contained 2254 participants, of whom 225 had a mean HbA_{1c} < 53 mmol/mol (7.0%) and 2029 had a mean HbA_{1c} ≥ 53 mmol/mol (7.0%). This cohort was used in an identical multivariate model and showed that the same factors were associated with increased HbA_{1c} variability independent of other variables when extreme HbA_{1c} values are removed (Table S3). The goodness-of-fit scores for the low and high mean HbA_{1c} strata were ($\chi^2 = 1014.87$, $P = 0.50$) and ($\chi^2 = 2058.30$, $P = 0.40$) respectively.

Creating five individual treatment categories in the second sensitivity analysis revealed that those treated with insulin were more likely to be highly variable than those who were taking triple oral therapy in the low mean HbA_{1c} strata; however, this was not seen in the high mean HbA_{1c} group (Table S4). It is important to note that a larger number of participants were taking triple oral therapy or insulin in the high mean HbA_{1c} strata ($n = 774$) compared with the low mean HbA_{1c} strata ($n = 73$).

Of the 9804 participants with a documented final drug therapy, 6165 did not change their treatment therapy from baseline and were included in the third sensitivity analysis. The findings from this analysis were in keeping with the results of the previous multivariate analyses (Table S5). Further analysis revealed that 11.2% of participants in the low variability group changed their treatment during the 4 years compared with 58.8% of those in the high variability group.

Discussion

The findings of our analysis revealed that young, insulin-resistant men are most at risk of having high HbA_{1c} variability. In addition, the participant's prescribed treatment was found to be the largest independent predictor of risk. These findings were seen in both the low mean and high mean HbA_{1c} groups. The choice of variability metric, whether SD or CV, had little effect on the results of our analysis.

Comparing our results with the most similar study identified in the field of short-term variability is of interest. Murata *et al.* [8] found in a cohort of 204 veterans with insulin-treated Type 2 diabetes that high glucose variability over 8 weeks was associated with older age and a longer diabetes duration. In addition, obesity and those treated with larger insulin doses were found to have lower variability. By contrast, we show the opposite findings for HbA_{1c} variability. The difference between the patient characteristics associated with short-term and long-term variability implies that the underlying mechanisms responsible may differ. This discovery further supports the role of visit-to-visit variability as a discrete entity of the glycaemic variability research field and provides a starting point for future work to understand the biological mechanisms responsible for raised HbA_{1c} variability.

We show that the people with Type 2 diabetes most likely to have highly variable HbA_{1c} are those with high BMI and

low HDL-cholesterol. This is of interest given the previously reported association of HbA_{1c} variability with increased risk of adverse outcomes including cardiovascular disease [3,4]. Our findings suggest that this association may not be causally related to HbA_{1c} variability, but might reflect the high cardiovascular disease risk characteristics of this cohort.

HbA_{1c} variability is likely to be caused by a number of factors, predominantly related to variability in lifestyle, such as exercise [16], high stress [17] and poor treatment adherence [18]. In addition to lifestyle factors, it is also likely that underlying biological mechanisms play a role in HbA_{1c} variability. For example, some people with Type 2 diabetes may be better than others at compensating for increased metabolic demands seen with episodic poor diet or illness. An extreme example of this can be found with glucokinase-maturity-onset diabetes of the young. These people with diabetes have impaired glucose-sensing abilities which results in mildly elevated blood glucose levels [19]. The HbA_{1c} readings of these individuals remain constant regardless of lifestyle and treatment interventions [20], consistent with these individuals being able to compensate for increased demand by increasing insulin secretion. The biological mechanisms underlying HbA_{1c} variability in Type 2 diabetes are not known, and further work is required in this area.

One potential limitation of our study was the positive correlation between mean HbA_{1c} level and HbA_{1c} variability. We wanted to draw associations based solely on HbA_{1c} variability, not mean HbA_{1c} level, which has previously proven associations with both micro- and macrovascular complications. To minimize this effect, we stratified the analysis by mean HbA_{1c} level. The results generated were consistent across both mean HbA_{1c} groups, strongly suggesting that the patient characteristics identified were associated with raised HbA_{1c} variability and not mean HbA_{1c} level. We also undertook a sensitivity analysis removing those with mean HbA_{1c} > 75 mmol/mol (9%) and < 48 mmol/mol (6.5%), and showed similar results to our full model. Another potential limitation to our model was underlying diabetes progression as those progressing rapidly will have a higher SD. To minimize the impact of progression we chose a 4-year window for HbA_{1c} readings to accurately assess long-term variability, while limiting the risk of falsely identifying fast progressors as having high HbA_{1c} variability. Finally, we acknowledge that this is an observational study, and although we have adjusted for potential measured confounders (such as social deprivation and number of HbA_{1c} measures) our results could still be affected by unmeasured confounders.

To determine HbA_{1c} variability, multiple HbA_{1c} readings are required. In this study, 1030 participants were excluded due to an insufficient number of HbA_{1c} measures, leaving a select group of people with Type 2 diabetes who have four or more HbA_{1c} readings over 4 years for further analysis. There are several potential clinical reasons why a person with

Type 2 diabetes may need to be monitored more closely than another which must be considered when interpreting our results. In this study, the number of readings was adjusted for in all our multivariate models and the baseline characteristics of this excluded cohort were similar to those of the participants included in our final analysis (Table S1).

Some 3639 participants changed their treatment over the 4-year window used to define HbA_{1c} variability, with treatment change being more common in the high variability group than the low variability group. This difference might reflect that those who are more variable are consequently more likely to receive additional treatment (as for a given mean HbA_{1c}, their HbA_{1c} readings are more likely to go high than those with low variability and this may precipitate new treatment). An alternative explanation is that starting a new drug results in a large change in HbA_{1c} that makes the HbA_{1c} recorded during these 4 years more variable (i.e. the HbA_{1c} variability is not a measure of intrinsic variability but is secondary to treatment change). To ensure that this latter scenario was not driving our results, a sensitivity analysis was carried out which showed almost identical results to our main analysis.

The treatment prescribed to a person with Type 2 diabetes was found to be strongly associated with their risk of having highly variable HbA_{1c}. This is particularly striking in the stratum with mean HbA_{1c} < 53 mmol/mol (7%). In this group, the participants who were intensively treated, with triple oral therapy or insulin, to achieve this target had a more than six-fold increased risk of having highly variable HbA_{1c}. Within this group, greater variability again was seen in those on insulin compared with triple oral therapy, although the numbers were small. A similar pattern is seen in the stratum with HbA_{1c} ≥ 53 mmol/mol (7%), although the effect is less strong and there is no greater risk of insulin treatment over triple oral therapy. These results are of interest, especially in the context of the outcomes of the ACCORD study where aggressive treatment initiated to achieve a treatment target of 48 mmol/mol (6.5%) resulted in increased mortality compared with a less aggressive target [21]. Our findings show that people with Type 2 diabetes who are treated intensively to reach a mean HbA_{1c} < 53 mmol/mol (7%) have much more variability between visits in their HbA_{1c} than those who are likely closer to diagnosis requiring no treatment or monotherapy. At this level, 11.5% of the participants with highly variable HbA_{1c} on triple oral therapy or insulin had at least one HbA_{1c} reading < 37 mmol/mol (5.5%); whereas 46.2% of the same cohort had a reading > 69 mmol/mol (8.5%). If HbA_{1c} variability per se is associated with increased risk of cardiovascular disease, this may explain the adverse outcomes found in ACCORD. Our findings support the rationale in the guidelines that emerged after ACCORD, that there should be a low HbA_{1c} target in those early in the disease process and a less aggressive target once treatment has intensified [15,22]. It should be noted, however, that our

analysis cannot ascribe a causal association between intensive treatment regimens and high HbA_{1c} variability. Individuals with high HbA_{1c} variability will have large fluctuations in HbA_{1c} that are likely to result in treatment intensification; conversely more intense treatment, especially with insulin, may result in more variability in glycaemic control.

In conclusion, we report, for the first time, the patient characteristics associated with high and low visit-to-visit variability in HbA_{1c}. We have shown that intensive treatment is associated with high HbA_{1c} variability, especially in those with a mean HbA_{1c} < 53 mmol/mol (7%). We also demonstrate that those with high HbA_{1c} variability are more likely to be male, younger and with low HDL-cholesterol. Further work is required to investigate how HbA_{1c} variability varies over the life course of someone's diabetes and with different diabetes treatments; and more complex models are required to account for underlying disease progression. Our findings suggest that those who are more likely to have high HbA_{1c} variability are those who have more cardiovascular risk factors. Given this, it is uncertain whether the adverse cardiovascular disease outcomes reported to be associated with increased HbA_{1c} variability can be attributed to the high HbA_{1c} variability per se, or more simply reflects the high cardiovascular risk factors seen in people with Type 2 diabetes who exhibit high HbA_{1c} variability. One potential way to unravel this causality question would be to use Mendelian randomization if suitable genetic instruments can be found.

Funding sources

The study was supported by the Wellcome Trust.

Competing interest

None declared.

Acknowledgements

We wish to acknowledge the help of the FARR Institute and the Health Informatics Centre, University of Dundee (Scotland, UK). E.R.P. holds a Wellcome Trust Investigator Award 102820/Z/13/Z.

Author contributions

J.D.N. analyzed data and wrote the manuscript. E.S.P. researched data and wrote the manuscript. L.A.D. analyzed data. E.R.P. planned the study, contributed to the discussion and reviewed/edited the manuscript.

Supporting Information

Additional Supporting Information may be found in the online version of this article:

Table S1. Baseline characteristics of included and excluded participants.

Table S2. Univariate whole sample analysis showing the odds of high HbA_{1c} variability.

Table S3. Sensitivity analysis 1: multivariate analysis showing the odds of high HbA_{1c} variability with extreme mean HbA_{1c} values removed.

Table S4. Sensitivity analysis 2: multivariate whole sample analysis showing the odds of high HbA_{1c} variability with further differentiation of treatment groups.

Table S5. Sensitivity analysis 3: multivariate analysis showing the odds of high HbA_{1c} variability with participants that changed treatment therapy removed.
