A multistakeholder approach to innovations in NAFLD care

Jörn M. Schattenberg¹, Alina M. Allen², Helen Jarvis³, Shira Zelber-Sagi^{4,5}, Ken Cusi⁶, John F. Dillon⁷, Cyrielle Caussy^{8,9}, Sven M. Francque^{10,11}, Zobair Younossi¹², Naim Alkhoury¹³ & Jeffrey V. Lazarus^{14,15,16}  

Non-alcoholic fatty liver disease (NAFLD) is highly prevalent globally and requires multidisciplinary care. Here, we report key findings of a NAFLD care workshop, address knowledge gaps and highlight a path to optimise healthcare resource use, to improve outcomes in patients with steatotic liver disease.

NAFLD, the most common chronic liver disease, affects around 33% of adults worldwide¹. Given the growing global prevalence of obesity and type 2 diabetes mellitus (T2DM), and their association with NAFLD, the burden of this liver condition and its socio-economic costs are only expected to grow².

NAFLD encompasses a disease spectrum that is defined on the basis of liver histology with fatty infiltration of liver tissue and gradual progression towards chronic inflammation (non-alcoholic steatohepatitis, NASH), fibrosis, cirrhosis and hepatocellular carcinoma (HCC)³. There are no approved therapies for NASH, but a growing evidence base supports the effectiveness of non-pharmacological interventions in halting progression or causing remission, highlighting the importance of early diagnosis and clinical management. Additionally, drugs licenced for cardiovascular disease (CVD), like statins, or T2DM, such as glucagon-like peptide 1 (GLP-1) receptor agonists and sodium-glucose cotransporter-2 inhibitors, hold early promise for NAFLD patients⁴.

However, NAFLD and NASH, along with other steatotic (fatty) liver diseases, are largely underdiagnosed worldwide and epidemiological data are scarce⁵, limiting the provision of good practice care and implementation of national preparedness plans. Furthermore, at present, liver biopsy is the most reliable method for diagnosing fibrosis and steatohepatitis, which is limited by cost, sampling error and procedure-related morbidity and mortality³, hindering clinical trials and drug development programmes. Several non-invasive tests (NITs), including serum and genetic biomarkers and imaging modalities, have been proposed as options for diagnosing NAFLD and NASH⁶.

NAFLD typically develops in the context of metabolic syndrome (MetS), which includes obesity, T2DM, dyslipidaemia and hypertension³. Comprehensive care therefore requires a

multidisciplinary and multistakeholder approach, to address the range of comorbidities affecting patients with NAFLD. Recent analyses have shown that a wide range of NAFLD models of care (MoCs) exist, varying in most aspects such as in who provides care, what care is provided considering the disease stage, which healthcare settings care is provided in and to what extent care is coordinated across the healthcare system⁷. Importantly, the availability of auxiliary healthcare services, such as peer-to-peer patient programmes, physician assistants or nurse practitioners, differs widely across healthcare systems.

National preparedness plans are deficient globally, indicating systemic gaps in delivering NAFLD care⁸. While adequate policies and civil society engagement, guidelines⁹, epidemiological data and care management are pivotal to the provision of good care, these are suboptimal to varying degrees in different countries, underscoring a need for dialogue among all relevant stakeholders, to prompt the integration of NAFLD into national public health agendas.

Building on a global public health and NAFLD consensus statement¹⁰, in May 2022, a multidisciplinary group of some 100 stakeholders met in Barcelona, Spain, and online, to exchange their experience on public health approaches to NAFLD and NASH. The discussions focused on diverse MoCs that currently exist or should be developed, in order to set out priorities for healthcare providers and policymakers, to optimise the diagnosis and management of NAFLD. This unique programme provided an interactive platform for primary care physicians, hepatologists, endocrinologists, nutritionists, public health experts, nurses and patients. Here, we summarise the discussions from this meeting.

The fatal triple

Obesity, T2DM and CVD are closely linked with and impact each other and NAFLD. However, each of these metabolic diseases also has its own unique features, resulting in several sub-types of patients that require a personalised, multidisciplinary approach (Fig. 1). Obesity is a major risk factor for NAFLD, and exposure to obesity increases the risk of HCC¹¹. NAFLD increases the risk of developing T2DM, whereas improvement of hepatic steatosis, or fat in the liver, decreases the incidence of T2DM¹². Furthermore, approximately 55% of patients with T2DM have NAFLD¹³. The presence of NAFLD in patients with T2DM hampers glycaemic control, requiring the use of multiple anti-diabetic therapies and increasing the risk of both micro- and macro-vascular complications¹⁴. The potential impact of NAFLD on CVD remains controversial. Several mechanisms can explain how NASH can impact the cardiovascular system, offering biological plausibility¹⁵. However, an independent contribution of NAFLD to the development of CVD is difficult to disentangle from the impact of other factors that are well-established risk factors for clinical CVD events, such as obesity, T2DM, dyslipidaemia and hypertension³. The majority of drugs used to prevent or treat CVD, e.g., statins, aspirin and other anti-aggrenant drugs, have benefit on the risk factors for NAFLD¹⁵, but therapies to treat NASH directly are required. Public health measures to address NAFLD include raising awareness and education, in addition to close collaboration between hepatologists, diabetologists, nutritionists and cardiologists, in care provision.

Screening and risk stratification

People admitted to hospital with decompensated cirrhosis, characterised by liver failure and/or liver-related issues like ascites or jaundice⁹, have a 25% chance of 60-day mortality; approximately 70% of new cirrhosis diagnoses are made on such an admission, making a case for the importance of early detection. Detection strategies based on case finding should focus on risk factors such as MetS features, like T2DM and obesity, or routinely performed liver function tests, and aim to improve the efficiency

Fig. 1 The fatal triple association between obesity, T2DM and CVD, and NAFLD.

The conditions are closely associated but without a complete overlap: the estimated prevalence of obesity among T2DM is approximately 80% in the US and the estimated prevalence of obesity among patients with NAFLD is 51% in Europe and the US. The prevalence of NAFLD among T2DM is approximately 55%, whereas the prevalence of NAFLD among patients with obesity varies from 50 to 90%, depending on the severity of obesity. The potential impact of NAFLD on CVD remains controversial, with several mechanisms explaining how NASH can impact the cardiovascular system; however, the independent contribution of NAFLD to the development of CVD is difficult to disentangle from the impact of other factors that are well-established risk factors for CVD. Given these interconnections, a personalised multidisciplinary approach is needed for the optimal care of patients with NAFLD. CVD cardiovascular disease, NAFLD non-alcoholic fatty liver disease, NASH non-alcoholic steatohepatitis, T2DM type 2 diabetes mellitus.

of existing patient interactions (e.g., automated laboratory measurement analysis to provide decision support to clinicians)¹⁶. The key to the success of such strategies is risk stratification by focusing on fibrosis markers, as the amount and pattern of fibrosis are indicators of disease progression⁹.

Both the European Association for the Study of the Liver and the American Gastroenterological Association recommend a two-tiered approach to risk stratification in those suspected or incidentally found to have hepatic steatosis on imaging, using sequential NITs (Fig. 2)^{17,18}. Although seemingly straightforward and consistent, the success of clinical pathways depends on the level of awareness and action in primary care and by other non-hepatology physicians, who must recognise risk factors, order liver enzyme tests, calculate and interpret NIT results and refer patients to specialists, when appropriate. Referral according to Fig. 2 will help to identify patients with end-stage liver disease and offer care in the context of clinical trials. Repeated testing over years can help decrease false negative rates in NAFLD which is, in general, slow progressing. Moving into the arena of precision medicine and supported by technological progress, risk prediction in the future will likely abandon indirect surrogate scores and incorporate the increasing knowledge on genetics and epigenetic changes, to benefit patients with advanced liver disease as a result of NAFLD. These caveats underscore the critical importance of developing and disseminating risk stratification approaches between multiple disciplines and providing robust data demonstrating improvement in patient outcomes in real-world settings.

NAFLD management in different settings

As NAFLD is a chronic multisystem disease, its prevention, detection and management require a multidisciplinary approach which should include primary care, hepatology, nutritionists, endocrinology, obesity medicine, bariatric surgery/endoscopy, psychology and

Fig. 2 Sequential risk stratification of patients with hepatic steatosis or metabolic risk factors. The sequential use of NITs aiming at the identification of patients with advanced liver disease, histologically defined as stages F2 and F3, allows in a first step to rule-out cases with advanced disease using the FIB-4 score. The presence of metabolic risk factors informs about the at-risk population. This will be crucial to enable the assignment of resources to the group with the highest risk of a detrimental outcome. Patients in the indeterminate category will need to be further evaluated by using a more refined second line test, including LSM or ELF. Patients in the high-risk category should be referred to specialists for further management. Based on the resources and availability of NITs, one-step testing strategies could be used in the future. ELF Enhanced Liver Fibrosis, LSM liver stiffness measurement, MRE magnetic resonance elastography, NIT non-invasive test.

Box 1 | Recommendations to enable and optimise a multidisciplinary approach in NAFLD care

- Evaluate the patient benefit and cost-effectiveness of multidisciplinary models of care based on non-invasive tests, which should be adopted by first-line providers, such as primary care physicians and endocrinologists, and monitor their use.
- Implement *context-specific* (prevention, screening, risk-stratification, treatment) and *resource-specific* (for low-, middle- and high-income settings) models of care and always report their effectiveness.
- Develop, provide and monitor clear guidance, endorsed by the relevant professional societies, regarding preventive hepatology and specific criteria for referral to specialty care such as hepatology, cardiology, endocrinology, obesity specialists, bariatric surgeons and exercise physiologists.
- Delivery models must overcome the time-constraints of primary care physicians and other doctors by decreasing the human burden (by using e.g., automated methods of screening and risk-stratification, multidisciplinary ‘metabolic’ clinics or training, virtual care, nurse coordinators across disciplines, web-based applications for longitudinal care, virtual assistants).
- Generate evidence to provide policy-makers the basis to recognise NAFLD as significant public health threat and allocate the appropriate resources to address it.
- The World Health Organization should integrate all types of steatotic liver disease into non-communicable disease technical guidance, action plans and strategies, setting out how to best implement a multidisciplinary approach.

NAFLD non-alcoholic fatty liver disease.

exercise physiology¹⁹ (Box 1). More studies are needed, but a multidisciplinary metabolic hepatology clinic approach has already proven to be effective, as patients with NAFLD experienced reductions in liver enzyme and stiffness levels and cardio-metabolic parameters like cholesterol, glucose and weight²⁰. At present, lifestyle interventions are the mainstay of available treatment.

Comprehensive MoCs need to incorporate such interventions and integrate and define the roles of primary, secondary and tertiary care throughout the patient’s prevention, detection and management journey⁷.

With a focus on holistic, comprehensive care and secondary prevention, primary care should be ideally placed to find and risk

stratify people with NAFLD, while recognising competing workload priorities, positioning NAFLD in the context of existing chronic disease management in different primary healthcare settings and reimbursement schemes and emphasising the need for integrated, centrally approved frameworks.

NAFLD care in the community needs to be part of a wider metabolic multimorbidity management approach, recognising the key role of the primary care nursing team and allied professionals with expertise in preventive hepatology and providing long-term nutrition and lifestyle interventions⁹. To drive change and optimise outcomes, ideal MoCs would include peer support and a role for a NAFLD/metabolic nurse specialist, to closely monitor disease management.

A crucial trigger for successful nutritional treatment is the active support of physicians. There is a vital role for healthcare providers as educators in explaining the importance of treating NAFLD (including in the broader context of T2DM, CVD and cancer prevention) and its potential to regress, teaching healthy eating skills, enhancing confidence in the benefits of diet, discussing potential barriers (e.g., life stressors and the obesogenic environment) and co-creating solutions²¹. Web-based interventions may be more inclusive and evidence indicates that web-based treatment tools are beneficial but dropout rates may be high and these may be more accessible to younger patients²². Further studies that integrate available technology with health applications are required.

Finally, although weight loss through traditional lifestyle modifications has been associated with the resolution of NASH and fibrosis regression²³, only a minority of patients can lose and maintain weight loss. Bariatric surgery leads to significant weight loss and resolution of NASH in the majority of patients and, more importantly, has been shown to reduce both major adverse cardiac events and liver outcomes²⁴. Non-surgical options include anti-obesity medications (AOMs), to support patients with NAFLD achieve and sustain their weight loss goals. Oral AOMs have low adherence rates, insufficient data on the histologic improvement of NASH/fibrosis and inconclusive data on their effects on the liver²⁵, making them less than ideal for achieving the desired weight loss in fibrotic NASH. Emerging evidence indicates that GLP-1 receptor agonists²⁶ can improve steatohepatitis, but it will remain to be determined if any compound meets the regulatory barrier of conditional approval. Whether through lifestyle, pharmaceuticals, surgery or a combination of these, weight management strategies should involve multidisciplinary input and be tailored to each patient.

Conclusions

Steatotic liver disease is a complex, multisystem disease that requires a multidisciplinary approach to prevention, diagnosis, treatment and care. Such an approach must be bottom-up, with key actors in the health system collaborating and developing efficient MoCs, and top-down, guided by national and global strategies. While no NAFLD- or NASH-specific treatment exists, structured lifestyle interventions and medications for related conditions can have positive effects, and many different stakeholders can and should play a role in improving health outcomes in patients with fatty liver disease.
